Abstract

1
2 Introduction: There is an academic dispute regarding the role of the right hemisphere in language
3
4 processing. TMS was used to test the hypothesis that Wernicke's area processes dominant meanings
5
6 ("teller") whereas its right homologue processes subordinate meanings ("river") of ambiguous
7
8 words ("bank"; Jung-Beeman, 2005).
9
10

11
12 Methods: Participants were asked to make a semantic decision on ambiguous words that were
13
14 followed either by unrelated words or by words associated with their dominant or subordinate
15
16 meanings. A 10Hz TMS train was applied on each trial over CP5 (left Wernicke), CP6 (right
17
18 Wernicke) or Cz (vertex) scalp positions, and was synchronized with the word presentation.
19
20

21
22 Results: Accuracy and d' analysis revealed a TMS LOCATION by MEANING interaction. TMS
23
24 over Wernicke's area resulted in more accurate responses and higher sensitivity to dominant
25
26 meaning blocks compared to stimulating the right Wernicke's area and the vertex. In contrast, TMS
27
28 over the right Wernicke's area resulted in more accurate responses and higher sensitivity to
29
30 subordinate meaning blocks, compared to stimulating the left Wernicke's area and the vertex.
31
32

33
34 Conclusion: The left and right Wernicke's areas function as processors of dominant and subordinate
35
36 meanings of ambiguous words, respectively. While previous research methods have yielded
37
38 indecisive results, TMS proved to be a useful tool in demonstrating a causal role of the two brain
39
40 regions in a double dissociation design with healthy subjects.

1
2 1. Introduction
3
4

5 More than a century ago, Broca (1865) and Wernicke (1874) argued that language is mainly a left
6 hemisphere (LH) function. Their clinical findings showed that the left but not the right hemisphere
7 lesions caused severe language impairments such as the inability to understand or generate speech.
8 More recently it has been shown that damage to the Right Hemisphere (RH) in the homologue areas
9 usually results in subtle language deficits such as impaired comprehension of jokes (Gardner et al.,
10 1975) or metaphors (Winner and Gardner, 1977).
11
12

13 Numerous models have been put forward to account for hemispheric differences (Dien, 2008) with
14 some overlap between theories. In the current study, we define hemispheric differences in semantic
15 processing as characterized by a tendency of the LH to process stimuli analytically (Levy-Agresti
16 and Sperry, 1968) when dealing with routine (Goldberg and Costa, 1981), frequent (Sergent, 1982)
17 and salient meanings (Giora, 2007). By contrast, the RH processes in a Gestalt mode (Levy-Agresti
18 and Sperry, 1968) and may perceive novel (Goldberg and Costa, 1981), infrequent (Sergent, 1982)
19 and non-salient (Giora, 2007) aspects of language. Jung-Beeman (2005) suggested that in the RH,
20 widespread groups of interconnected neurons are activated by lingual stimuli, whereas such stimuli
21 activate a more restricted group of neurons in the LH. This restricted activation enables fine
22 encoding in the LH which is appropriate when the precise, frequent meaning of a term is required.
23
24

25 In a complementary fashion, the coarser processing in the RH may be useful when words are
26 remotely associated (Giora, 2007). However the evidence to support the fine-coarse coding theory
27 (Jung-Beeman, 2005) is correlational at best since it is drawn from the few existing fMRI studies.
28
29

30 As a test case to reveal potential hemispheric differences in semantic processing we studied
31 ambiguous words that have a subordinate meaning in addition to their dominant, frequent meaning.
32
33

34 Based on brain lesion observations (Gardner and Brownell, 1986) and divided visual field studies
35 with healthy participants (Burgess and Simpson, 1988) it has been suggested that the RH has a

64
65

1 special role in lexical ambiguity resolution. However, these research methods were unable to
2 identify the specific region within the RH that participates in the process.
3

4 In contrast, today's imaging studies can contribute to finer localization of RH language centers.
5

6
7 Rodd et al. (2005) contrasted auditory sentences containing ambiguous words (The *shell* was *fired*
8 towards the *tank*) with matched sentences that did not contain ambiguous words. Although the
9 study did not distinguish between subordinate and dominant meanings, the results showed that
10 along with Broca's region and Wernicke's area (in the LH), the right homologue of Broca's region
11 (the triangular and opercular parts of the right inferior frontal gyrus) were also activated by
12 ambiguity. Since activation in the regions of interest was the dependent variable, it is impossible to
13 determine whether the ambiguous stimuli caused RH activity which resulted in comprehension, or
14 whether the ambiguous stimuli caused RH activity but comprehension was achieved independently
15 by another neuronal mechanism. EEG studies have revealed that ambiguous word processing
16 modulates the N400 ERP component under certain contextual conditions. Sitnikova et al. (2003)
17 showed that the N400 component is more negative for an incongruent context of ambiguous words
18 than a congruent context (see also Titone and Salisbury, 2004). This interaction was found for
19 healthy subjects, and not patients with schizophrenia, a disease known to cause impaired processing
20 of ambiguous words (Chapman et al., 1976). While these studies are informative as to the timing of
21 neuronal processes, they cannot establish clear cut causal inferences regarding the role of the
22 neuronal generator of the N400 component and the observed behavior, or shed light on the locus of
23 the function.

47

48 Transcranial Magnetic Stimulation (TMS) has been used to locate language brain centers in simple
49 tasks such as picture naming that do not normally call for RH involvement, similar to intraoperative
50 methods which are used to prevent postoperative aphasia (Duffau et al., 2002; Eisner et al., 1996;
51 Herholz et al., 1997; Ojemann, 1979; Ojemann et al., 1989; Rutten et al., 2002).

65

1 Two noninvasive TMS procedures have been used to assess the functionality of Wernicke's area.. In
2 one case, high frequency (20Hz) stimulation decreased latency when applied during a naming task
3 immediately before each trial (Mottaghy et al., 1999; Sparing et al., 2001). By contrast a 10-minute
4 low frequency (1Hz) TMS train applied prior to the task (picture-name verification) resulted in
5 inhibition (Drager et al., 2004; Flöel et al., 2000; Knecht et al., 2002). This suggests that Wernicke's
6 region is enhanced by event-related high frequency TMS delivered during a behavioral experiment,
7 and inhibited by offline low frequency TMS. Note that the TMS effect depends on location, task,
8 intensity and frequency (Bestmann, 2008). Repetitive high frequency protocols may result in
9 language inhibition if applied over different brain regions (e.g., Stewart et al., 2001), and similarly,
10 low frequency offline protocols may yield a facilitation of language processing (Drager et al.,
11 2004).

12 Both of these TMS protocols can be used to explore the causal role of brain regions. If language
13 function is indifferent to neuronal activity in any brain region, then neither excitation nor inhibition
14 of neurons in that region should alter behavior. Inhibitory and excitatory TMS effects can be
15 thought of as higher and lower thresholds for neuronal activity in the stimulated region; Neuronal
16 input which normally causes neurons to fire will not suffice if the threshold was elevated by
17 inhibitory TMS, whereas weak neuronal input may result in action potentials if the threshold was
18 lowered by excitatory TMS. We chose an event-related design to explore the spatial and temporal
19 characteristics of semantic processing. Following previous studies with similar protocols, we
20 predicted facilitation following CP5/CP6 high frequency event-related stimulation.

21 We used a semantic decision task where participants were asked to decide whether an ambiguous
22 word was related or not to a subsequent word. The following word could be related to the dominant
23 or subordinate meaning of the ambiguous word or not related at all.

2. Methods

2.1. Participants

Six female and 5 male students with no history of neurological illness participated after giving their informed consent. All were right handed (scoring at least 90 on the Edinburgh Handedness inventory (Oldfield, 1971) and native Hebrew speakers. Their sight was normal or corrected to normal, and their age ranged from 20 to 36 years. They received an fee equivalent to \$ 40 for participating in the two hour experiment.

2.2. Design

A factorial $2 \times 3 \times 2$ design was applied, with BLOCK MEANING (dominant, subordinate), TMS LOCATION (left Wernicke, vertex, right Wernicke) and RELATEDNESS (related, unrelated) as within subject factors.

2.3. Visual stimuli

A list of 60 ambiguous Hebrew words, whose dominant and subordinate meanings had been validated in previous studies (Faust and Kahana, 2002; Peleg and Eviatar, 2008) was used. Each ambiguous word was presented once with a dominant association, once with a subordinate association and between 1 to 3 times with an unrelated word, a different one in each trial. The unequal number of repetitions aimed to prevent subjects from guessing the remaining number of positive responses for a given stimulus (e.g., reasoning such as "since 'bank' appeared twice with related associations next it will appear with an unrelated word"). The association words were taken from Peleg and Eviatar (2008) matched on latencies in a simple lexical decision task involving 36 subjects. The stimuli were matched on the basis of RT given the lack of frequency norms in Hebrew. The words were presented in the center of the screen in Courier New , 18 such that the average stimulus subtended 3.47° .

2.4. TMS procedure

1
2 TMS was applied in accordance with conventional safety regulations (Wassermann, 1998) using
3
4 a Super-Rapid Magstim stimulator with about 2T maximum output, and a figure- 8 coil (outer
5
6 diameter 70 mm). The procedures were approved by the Bar Ilan University Ethics committee.
7
8
9 Subjects wore a Lycra hat and were requested to place their hands on their thighs with the palms
10
11 facing up. For each subject the optimal scalp location for induction of visible contraction of finger
12
13 muscles was identified for each hemisphere. A single-pulse TMS was then applied at decreasing
14
15 intensities over these sites to determine the motor threshold for each hemisphere, defined as the
16
17 minimal intensity required to induce 6 visible motor responses out of 12 (Baudewig et al., 2001;
18
19 Rusconi et al., 2005; Stewart et al., 2001). CP5 and CP6 scalp positions were then marked on the
20
21 Lycra hat according to the EEG 10-20 system to indicate the stimulation sites to be used during the
22
23 semantic task. These positions were correlated with the left and right Wernicke's areas, respectively
24
25 (Flöel et al., 2000; Sparing et al., 2001). TMS was applied at 100% of the motor threshold intensity
26
27 for the same hemisphere.

35

2.5. Apparatus and Procedure

36
37 Participants came to the lab twice, with a one- week interval between sessions. In each session,
38
39 one hemisphere was stimulated twice, once in a dominant meaning block and once in a subordinate
40
41 meaning block, where each block contained 40 trials. The second hemisphere was stimulated in the
42
43 second session, in the same MEANING order. A control block was run in the middle of each
44
45 session with half a block in the first meaning condition and the second half in the second meaning
46
47 condition, while stimulating the vertex. Meaning order, location order and stimuli lists were
48
49 counterbalanced across subjects.

64
65

1 The task was practiced in a 24 trial- session during the first session, with the same meaning order
2 used throughout the experiment, with visual feedback for responses but without TMS. Six TMS
3 trials followed for practice. The stimulus display was controlled by E-prime 1.1 software
4 (Psychology Software Tools, Inc., PA, US). Each trial started with a fixation cross presented for
5 700msec, followed by an ambiguous word presented for 750msec, a 50msec blank screen, a
6 500msec fixation cross and presentations of an associated or an unrelated word for 190msec. A
7 500msec TMS train was applied at the onset of the association word. Responses were recorded for
8 1810msec following the second word offset during which a blank screen was displayed, followed
9 by a 500msec gray screen presented as preparation for the next trial sequence (see Figure 1).

25

26 3. Results 27

28 Repeated measure ANOVAs were run separately for correct RT and accuracy, with BLOCK
29 MEANING (dominant, subordinate), RELATEDNESS (related, unrelated) and TMS site (CP5, Cz,
30 CP6) as within subject factors.
31
32
33

34 3.1 Accuracy 35

36 The main effect for BLOCK MEANING was significant with a higher accuracy rate for dominant
37 (.92) compared to subordinate meaning blocks (.87; $F(1,10)=6.48, p=0.029$). More importantly, the
38 BLOCK MEANING by TMS LOCATION interaction was significant ($F(2,20)=10.993, p<.001$).
39 Planned comparisons revealed that LH stimulation increased accuracy rates in dominant meaning
40 blocks compared to the other two locations ($t(10)=3.92, p=.0029$), whereas stimulating the RH
41 increased sensitivity in subordinate meaning blocks compared to the other two locations
42 ($t(10)=2.81, p=.018$); see Fig. 2A. No further effects were significant ($p>.12$).

57
58

59 3.2 Signal detection analysis 60 61 62 63 64 65

1 D' was calculated for the 3 TMS LOCATIONS \times 2 MEANINGS for each subject. The MEANING
2 \times TMS LOCATION interaction was significant ($F(2,16)=8.01$, $p = .0039$) with no further
3
4 significant results ($p > .16$). Planned comparisons revealed that LH stimulation increased sensitivity
5
6 in dominant meaning blocks compared to the other two locations ($t(8)=2.81$, $p = .011$), whereas
7
8 stimulating the RH increased sensitivity in subordinate meaning blocks compared to the other two
9
10 locations ($t(8)=1.86$, $p = .049$); see Fig. 2B).
11
12

13 (Insert Figure 2 about here)
14
15
16
17
18

19 3.3 RT 20 21

22 The main effect for MEANING was significant ($F(1,10)=6.10$, $p=.033$) with faster responses for
23
24 dominant (854msec) compared to subordinate meaning trials (926msec). The main effect for
25
26 RELATEDNESS was also significant ($F(1,10) = 24.4$, $p < .001$). No further effects were significant.
27
28 There was a trend toward a RELATEDNESS by MEANING interaction ($F(1,10)=3.30$, $p=.099$)
29
30 with a greater advantage of dominant over subordinate blocks for related (85msec) than for
31
32 unrelated trials (55msec). All the other main effects and interactions yielded p values over .4.
33
34
35
36
37
38

39 4. Discussion 40 41

42 The aim of the current study was to explore the involvement of the right homologue of
43
44 Wernicke's area in the processing of subordinate meanings of ambiguous words. It has been claimed
45
46 that the left and right hemispheres focus on processing the dominant and subordinate meanings of
47
48 ambiguous words, respectively, however a causal relationship between the hemispheres and
49
50 meaning types could not be established with certainty. We used TMS to demonstrate causal links
51
52 between cortical areas and cognitive functions. Since we used a high frequency event related
53
54 protocol which in previous studies of CP5 scalp position resulted in facilitation of behavior, we
55
56 expected performance to be facilitated while stimulating the expert hemisphere for the same
57
58
59
60
61
62
63
64
65

1 meaning condition. As predicted, responses in the experimental blocks that contained dominant
2 meanings were more accurate when TMS was applied over Wernicke's area, as compared to
3 stimulating the right homologue of the same area or the vertex. The opposite pattern emerged for
4 subordinate meaning blocks, with more accurate responses when stimulating the right homologue of
5 Wernicke's area compared to the other two locations. The interaction of BLOCK MEANING and
6 TMS LOCATION was significant over and above the RELATEDNESS conditions; i.e., for related
7 as well as for unrelated trials. This pattern of results implies that when subordinate meanings of
8 ambiguous words are expected (which is a consequence of the block design), the RH is not only
9 involved in deciding that a word pair is semantically associated but also in negating such an
10 association when it is absent. This finding is intriguing since little is known about negation
11 processes in the brain. It has been suggested that in the processing of complex language functions
12 such as irony, which can be seen as a form of negation (Giora, 1995), the right hemisphere plays a
13 role (Gardner and Brownell, 1986; Giora et al., 2000).

14 We argue here that the facilitative TMS effects we found suggest a causal role for the right and left
15 Wernicke's areas in processing subordinate and dominant meanings of ambiguous words,
16 respectively. When conceptualizing TMS effects as adding neuronal noise, an alternative
17 interpretation might be that the TMS actually inhibited the stimulated areas. Their inhibition
18 decreased inhibitions these areas might have over other areas (in a dis-inhibition mechanism),
19 where these distant areas are involved in processing lexical ambiguity rather than the areas that
20 were directly stimulated. However such interpretation is not supported by previous studies of
21 Topper et al. (1998), where they found facilitation for picture naming while stimulating left
22 Wernicke's area, which cannot be explained by inhibitory processes.

23 TMS applied to a single area can have either a positive or a negative effect depending on the rate of
24 stimulation (Walsh and Rushworth, 1999). Causality, however, is always assumed when a
25 significant TMS effect occurs (whether facilitative or inhibitory) as there is brain imaging evidence

1 showing that TMS coincides with a critical epoch of cortical processing. Paus et al. (1997), for
2 example, found an increase in cortical synaptic activity as indexed by increased regional cerebral
3 blood flow (rCBF) in the cortex below the point of magnetic stimulation that had a facilitative effect
4 on performance. In accordance, Silvanto and Muggleton (2008) suggested that TMS effect is
5 increasing excitability of neurons rather than adding neuronal noise.
6

7
8
9
10
11 In terms of signal detection theory (Egan, 1975), stimulating the expert hemisphere (the LH in
12 dominant blocks and the RH in subordinate blocks) increased sensitivity (d') to associations
13 between words because both miss errors (related trials) and false alarm errors (unrelated trials) were
14 reduced compared to the findings when stimulating the non-expert hemisphere and the vertex (Fig
15 2B.). The predicted double dissociation was found: TMS over Wernicke's area resulted in a more
16 accurate detection of dominant meaning associations, whereas stimulating Wernicke's right
17 homologue resulted in a more accurate detection of subordinate meaning associations.
18

19
20
21
22
23
24
25
26
27
28
29 It could be argued that the TMS over the RH location actually reduced RH activity but still
30 increased accuracy for subordinate meanings by an increased activation of LH language. If so, RH
31 stimulation should also facilitate dominant meaning processing in the LH, but in fact RH TMS
32 yielded the lowest accuracy rates for dominant meaning blocks. If this trend, which was not
33 significant in the current study, is found to be significant in future studies, this would imply that the
34 right Wernicke's area is not only involved in processing subordinate meanings but also in
35 suppressing dominant meanings in the left Wernicke's area.

The current study contributes to functional brain mapping by revealing, for the first time, the important role the right Wernicke's area plays in processing subordinate meanings of ambiguous words, and hence lends weight to Jung-Beeman's theory (Jung-Beeman, 2005). Rodd et al. (2005) did not specify this region as responsive to ambiguity in their fMRI study, but this could be due to the use of a different task and stimuli which involved sentential context where no distinction was made between dominant and subordinate meanings. It may also be that both right Broca (Rodd et

1 al., 2005) and Wernicke's right homologues (the current work) participate in ambiguity processing
2 but the fMRI only measured the input to the right Broca's region and not the source of the signal
3
4 (Logothetis et al., 2001) that may have come from the right Wernicke's area (Matsumoto et al.,
5
6 2004). A study combining TMS with EEG, or TMS with fMRI may shed light on this question of
7
8 connectivity (Bestmann, 2008).
9

10
11 The current study only answers the "when" question to a limited extent. Accuracy was improved
12
13 while five magnetic pulses were given at time 0, 100, 200, 300 and 400msec from target onset,
14
15 showing that the activity of the left or right Wernicke's area (depending on the expected meaning) is
16
17 important for the task during this time interval, which is congruent with previous EEG results
18
19 (Sitnikova et al., 2003; Titone and Salisbury, 2004). In order to provide better time resolution in
20
21 future experiments a single pulse design at various points in time could be used (Skarratt and
22
23 Lavidor, 2006).
24
25
26

27
28 Since the meaning was manipulated between blocks, it is possible that participants noticed when
29
30 set-shifting from responses to dominant meanings to a search for subordinate meaning was
31
32 necessary. This shift from automatic, LH processing to global, RH processing can be seen as a top-
33
34 down influence since the expectation of a certain stimulus leads to a different semantic
35
36 interpretation of words. Since the frontal lobes are necessary for set-shifting (Konishi et al., 1998;
37
38 Pantelis et al., 1999) the shift from LH to RH processing may take place in the frontal lobes. The
39
40 finding that schizophrenia is characterized by deficits in frontal lobe functioning (Andreasen et al.,
41
42 1992), together with impairments in set-shifting (Gold et al., 1997) and in subordinate meaning
43
44 processing (Chapman et al., 1976), strengthens this hypothesis.
45
46
47
48

49
50 Individual differences in language lateralization were ignored in this study, but it may be
51
52 worthwhile to check in future TMS studies whether individuals who have a RH dominance for
53
54 language, as determined by fMRI or fTCD (Flöel et al., 2000), use their left Wernicke's area to
55
56 process non-salient meanings. The paradigm can also be applied to explore abnormal brain
57
58
59
60
61
62
63
64
65

1 asymmetry in schizophrenia. If the reported deficit in ambiguity processing of schizophrenic
2 patients (Chapman et al., 1976) is a consequence of the inability to use the RH (Mitchell and Crow,
3 2005), stimulating the right, but not left Wernicke's area may temporarily restore the patients'
4 subordinate meaning processing to normal. Further studies are needed to assess the precise effect of
5 stimulation on brain activity. TMS interleaved with fMRI can reveal whether stimulation results in
6 callosal inhibition, or possibly in intra-hemispheric facilitation of other language regions.
7

8
9
10
11
12
13
14 In summary, functional mapping was carried out by using a method that allowed for an inference of
15 causality in healthy brains. The effect of stimulating the left and right Wernicke's areas was
16 symmetric in nature. TMS induced neuronal activity in the left and right Wernicke's areas, which
17 resulted in increased accuracy for dominant and subordinate meaning blocks, respectively. Further
18 experiments should explore connectivity with other regions, better time resolution and possible
19 medical applications.

Figure 1.

An illustration of the timeline in a typical trial presenting a related trial in a subordinate meaning block. Each trial started with a fixation cross presented for 700msec, followed by an ambiguous word presented for 750msec (PEN in this example), a 50msec blank screen, a 500msec fixation cross and an associated or an unrelated word presented for 190msec (FARMER). A 500msec TMS train of 10Hz was applied with the onset of the association word. Responses were registered during 1810msec following the second word offset while a blank screen was displayed, followed by a 500msec gray screen presented as a pre-cursor for the initiation of the next trial sequence.

Figure 2.

Accuracy rates (A) and sensitivity (B) as a function of TMS LOCATION and BLOCK MEANING. Accuracy and d' were selectively modified by the magnetic stimulation. In dominant meaning blocks, Accuracy rates and d' were higher when the coil was placed over Wernicke's region compared to the other two locations, whereas in subordinate meaning blocks, Accuracy and d' were higher when the coil was placed over the right homologue of Wernicke's region compared to the other two locations. *p<0.05, **p<0.01. Error bars delineate standard errors, RT values in msec are detailed in the bottom of Fig 2A.
